## ABSTRACT

A highly active and selective GaZrO<sub>x</sub>/SAPO-34 bifunctional catalyst was developed for CO<sub>2</sub> hydrogenation into C<sub>2</sub>=C<sub>4</sub>. A high C<sub>2</sub>=C<sub>4</sub> selectivity of 88.8% at CO<sub>2</sub> conversion of 26.7% was achieved, and the olefin yield reached 11.3%, outperforming the previous reports. As Ga:Zr atomic ratio increases, the surface oxygen vacancy content (O<sub>v</sub>), responsible for CO<sub>2</sub> activation, firstly increases from 22.5% to 32.6% and then decreases to 15.4%, while the H<sub>2</sub> dissociation ability produced by Ga site increases gradually. Activated CO<sub>2</sub> at Zr–O<sub>v</sub>–Zr site could either react with Ga–H<sup>δ−</sup> to form HCOO\*, then successive hydrogenation to CH<sub>3</sub>O\* intermediate, or combine with O–H<sup>δ+</sup> to form COOH\*, followed by dissociation to form CO. The formation of CH<sub>3</sub>O\* or CO is competitive, which highly depends on the H<sub>2</sub> dissociation ability, only the moderate H<sub>2</sub> dissociation ability benefits CO<sub>2</sub> hydrogenation to CH<sub>3</sub>O\* at high temperature, leading to a high C<sub>2</sub>=C<sub>4</sub> yield.

## 1. Introduction

The utilization of CO<sub>2</sub> to synthesize light olefin (C<sub>2</sub>=C<sub>4</sub>), the crucial raw material in chemical industry, has attracted great attentions in recent years [1,2], which could not only mitigate the climate change caused by CO<sub>2</sub> emission, but also provide a new sustainable synthesis route to reduce the consumption of fossil fuels [3]. By employing Fe-based catalysts, CO<sub>2</sub> is firstly converted to CO via reverse water gas shift (RWGS) reaction, followed by hydrogenation of CO to C<sub>2</sub>=C<sub>4</sub> via Fischer-Tropsch to olefin synthesis route (FTO) [4,5], but, the selectivity of C<sub>2</sub>=C<sub>4</sub> hardly exceed 60%, which is limited by the Anderson-Schulz-Flory (ASF) rule [6].

Recently, bifunctional catalysts composed of metal oxide and zeolite are employed to catalyze CO<sub>2</sub> hydrogenation into C<sub>2</sub>=C<sub>4</sub> with high selectivity of ~80% in the hydrocarbon products [1,7–9]. In this catalytic route, the hydrogenation of CO<sub>2</sub> occurs on the surface of metal oxide to form CH<sub>x</sub>O (CH<sub>3</sub>O\*, CH<sub>3</sub>OH) intermediate, and then converts into C<sub>2</sub>=C<sub>4</sub> by the zeolite's acidic sites. The C–C coupling of CH<sub>x</sub>O over zeolite requires the reaction temperature of about 400 °C [10], however, such high reaction temperature results in the formation of CO via RWGS reaction as the dominant product rather than the CH<sub>x</sub>O intermediate over metal oxide [9]. As a result, reducing the selectivity of total

hydrocarbon products, the obtained yield of C<sub>2</sub>=C<sub>4</sub> was normally less than 7% [11–16]. For example, by employing Zn-Zr/SAPO-34 catalyst [11], the C<sub>2</sub>=C<sub>4</sub> selectivity reached as high as 80% in hydrocarbon products at CO<sub>2</sub> conversion of 18% (400 °C, 2.0 MPa), but the CO selectivity was 65%, leading to the low C<sub>2</sub>=C<sub>4</sub> yield of 5.0%. By employing In-Zr/SAPO-34 catalyst [13], the CO<sub>2</sub> conversion reached as high as 35.5%, and the C<sub>2</sub>=C<sub>4</sub> selectivity was 76.4% (400 °C, 3.0 MPa), but the C<sub>2</sub>=C<sub>4</sub> yield was only 5.4%. The reason is that the most of CO<sub>2</sub> converts to CO, about 80%, and only 7.1% to hydrocarbons. Since the higher CO<sub>2</sub> conversion is always along with the higher CO selectivity, it is necessary, albeit very challenging, to develop the novel metal oxide catalyst to boost the selective conversion of CO<sub>2</sub> to CH<sub>x</sub>O instead of CO at high temperature, and further enhance the C<sub>2</sub>=C<sub>4</sub> yield after combined with SAPO-34 zeolite.

Extensive studies have revealed that the oxygen vacancy on the metal oxide surface benefits the CO<sub>2</sub> adsorption, activation and to form CH<sub>3</sub>OH intermediates [17–20]. Liu et al. reported that over the ZnGa<sub>2</sub>O<sub>4</sub> catalyst, the increase of density of oxygen vacancy linearly enhanced the formation rates of methanol/dimethyl ether [15]. Density functional theory (DFT) calculations revealed that the oxygen vacancy created by incorporation of Zr to In<sub>2</sub>O<sub>3</sub> surface facilitates to form and stabilize CH<sub>3</sub>OH while strongly suppress the CO formation [13]. It is indicated

<sup>1</sup> These authors contribute equally to this work.

that abundant and special oxygen vacancy of metal oxides is essential to boost the conversion of  $\text{CO}_2$  to  $\text{CH}_x\text{O}$ , consequently to increase the  $\text{C}_2^- - \text{C}_4^-$  yield. It is well known that  $\text{ZrO}_2$  surface easily produce sufficient oxygen vacancy to activate  $\text{CO}_2$  [21–25], but it has a little  $\text{H}_2$  activation ability [26]. Therefore, adding another component with hydrogen dissociation ability to  $\text{ZrO}_2$  is essential for  $\text{CO}_2$  hydrogenation to  $\text{CH}_x\text{O}$  such as  $\text{ZnO}$  [27],  $\text{In}_2\text{O}_3$  [24],  $\text{CdO}$  [19]. In addition to these oxides,  $\text{Ga}_2\text{O}_3$  has the similar property to activate the  $\text{H}_2$  with heterolytic dissociation [28,29]. Pan et al. found that high temperature facilitates the  $\text{H}_2$  dissociation on  $\text{Ga}_2\text{O}_3$  and produce  $\text{GaH}$  species [29]. Our recent work found that  $\text{Ga}_2\text{O}_3$  provides a proper  $\text{H}_2$  dissociation ability to boost the conversion of syngas into light olefin by employing Ga-Mn oxide/SAPO-34 [30]. Witton et al. reported that the adding Ga to  $\text{In}_2\text{O}_3$  benefits the  $\text{CO}_2$  hydrogenation to methanol and suppress the RWGS reaction at high temperature [18]. It is suggested that  $\text{GaZrO}_x$  with SAPO-34 perhaps have an excellent catalytic activity and selectivity to synthesize  $\text{C}_2^- - \text{C}_4^-$  from  $\text{CO}_2$  hydrogenation. To the best of our knowledge, there has been no research reports on this catalyst and the synergistic effect of Zr and Ga on  $\text{CO}_2$  hydrogenation to  $\text{C}_2^- - \text{C}_4^-$  is unclear.

In this work, the binary  $\text{GaZrO}_x$  with SAPO-34 catalyst for  $\text{CO}_2$  hydrogenation into  $\text{C}_2^- - \text{C}_4^-$  was investigated. The structure, physico-chemical properties, and electronic properties of  $\text{GaZrO}_x$  with different Ga:Zr atomic ratios were characterized to reveal the relationship between the structure and activity. The  $\text{CO}_2/\text{H}_2$  adsorption, activation, and the hydrogenation mechanism were discussed.

## 2. Experimental section

### 2.1. Catalytic preparation

A series of  $\text{GaZrO}_x$  with different Ga:Zr atomic ratios (1:16, 1:8, 1:4, 4:1) as well as the sole  $\text{ZrO}_2$ ,  $\text{Ga}_2\text{O}_3$  were prepared via parallel flow coprecipitation method. Typically, the required amount of  $\text{Zr}(\text{NO}_3)_2 \cdot 5\text{H}_2\text{O}$  and  $\text{Ga}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$  were dissolved in deionized water to form a mixed salt solution with total concentration of Ga and Zr for  $1.0 \text{ mol} \cdot \text{L}^{-1}$ . An aqueous solution of ammonia ( $1.0 \text{ mol} \cdot \text{L}^{-1}$ ) was prepared as the precipitation agent. Then they were simultaneously added dropwise to 100 mL deionized water under continuous stirring at  $30^\circ\text{C}$ . The pH value of the aqueous solution was kept at  $7.0 \pm 0.1$  by adjusting the addition rate of the basic solution, the obtained suspension was aged for 1 h at  $60^\circ\text{C}$ , and then centrifuged, washed with deionized water until neutral. Finally, the precipitate was dried at  $110^\circ\text{C}$  for 12 h, and calcined in air at  $450^\circ\text{C}$  for 4 h. The obtained samples for  $\text{GaZrO}_x$  with various Ga:Zr atomic ratios were named as Ga:Zr(m:n), where m:n is the atomic ratio of Ga:Zr.

SAPO-34 zeolite was hydrothermally synthesized as presented in our previous reports [30]. More information about the SAPO-34 preparation is given in Supporting information (SI).

Bifunctional catalyst was prepared by mortar-mixing configuration, in which the SAPO-34 and  $\text{GaZrO}_x$  oxides with a mass ratio of 1:2 were grounded in an agate mortar for 10 min to mix well, and then pressed and crushed into 20–40 mesh particles.

### 2.2. Catalyst characterization

The samples were characterized by X-ray diffraction (XRD); Raman spectra; Time-of-flight secondary ion mass spectrometry (TOF-SIMS); X-ray photoelectron spectroscopy (XPS); Electron paramagnetic resonance (EPR); Temperature-programmed desorption of  $\text{CO}_2$  ( $\text{CO}_2$ -TPD); Transmission electron microscopy (TEM) and EDX mapping; *In-situ* diffuse reflection infrared Fourier transform (in-situ DRIFT). More information about the catalyst characterization is given in SI.

### 2.3. DFT calculations

Spin-polarized density functional theory (DFT) calculations were implemented by the Vienna Ab Initio Simulation Package (VASP) code [31,32], and the projector augmented wave (PAW) method have been employed. Details are presented in SI.

### 2.4. Catalytic activity test

The reaction of direct hydrogenation of  $\text{CO}_2$  into  $\text{C}_2^- - \text{C}_4^-$  was tested on a high-pressure fixed-bed reactor. Typically, 0.4 g of bifunctional catalyst was loaded in the quartz tube with inner diameter of 6.0 mm embedded in stainless steel tubular reactor. Prior to reaction, the catalyst was pretreated in the  $\text{H}_2$  flow ( $20 \text{ mL} \cdot \text{min}^{-1}$ ) for 4 h at  $390^\circ\text{C}$ , and then the mixed gas ( $\text{CO}_2/\text{H}_2/\text{N}_2 = 24:72:4$ ) was introduced. The reaction was carried out under  $390^\circ\text{C}$ , 3.0 MPa, and  $3000 \text{ mL} \cdot \text{h}^{-1} \cdot \text{g}^{-1}$  unless otherwise stated.  $\text{N}_2$  was used as an internal standard gas to ensure an accurate carbon balance. Details about the products analysis are presented in SI.

## 3. Results and discussion

### 3.1. Catalytic activity evaluation

The methanol synthesis ( $\text{CO}_2 + 3 \text{H}_2 \rightarrow \text{CH}_3\text{OH} + \text{H}_2\text{O}$   $\Delta H_{298}^0 = -45.9 \text{ kJ} \cdot \text{mol}^{-1}$ ) and RWGS reaction ( $\text{CO}_2 + \text{H}_2 \rightarrow \text{CO} + \text{H}_2\text{O}$   $\Delta H_{298}^0 = 42.1 \text{ kJ} \cdot \text{mol}^{-1}$ ) usually occur simultaneously, whereas the latter is more competitive at high temperature, according to the equilibrium calculations, the equilibrium selectivity of CO reaches 99.3% at  $390^\circ\text{C}$ , 3.0 MPa (Fig. S1a), compared with the methanol synthesis reaction, the hydrogenation of  $\text{CO}_2$  into  $\text{C}_2^- - \text{C}_4^-$  is thermodynamically more favorable, the equilibrium selectivity and yield of olefin (represented by ethylene) is 94.0% and 55.5% at  $390^\circ\text{C}$ , 3.0 MPa (Fig. S1b). It means combining methanol synthesis reaction with MTO reaction can decrease the selectivity of CO and promote  $\text{C}_2^- - \text{C}_4^-$  formation. Fig. 1 shows the performance of  $\text{CO}_2$  hydrogenation into  $\text{C}_2^- - \text{C}_4^-$  over bifunctional catalysts. The effect of different Ga:Zr atomic ratios on catalytic performance is displayed in Fig. 1a, the sole  $\text{ZrO}_2$  combined with SAPO-34 shows a high  $\text{C}_2^- - \text{C}_4^-$  selectivity of 82.4% in hydrocarbon, but the obtained yield of  $\text{C}_2^- - \text{C}_4^-$  is only 0.2%, which is due to the low  $\text{CO}_2$  conversion of 9.6% and high CO selectivity of 97%. A small amount of Ga (Ga:Zr=1:16) significantly enhances the  $\text{CO}_2$  conversion and  $\text{C}_2^- - \text{C}_4^-$  yield, further increasing Ga:Zr atomic ratio, the volcano-type curves are obtained; Meanwhile, the CO selectivity, which produced from RWGS reaction, exhibits an inverted volcanic result as compared with  $\text{CO}_2$  conversion and  $\text{C}_2^- - \text{C}_4^-$  yield.  $\text{GaZrO}_x$  with the Ga:Zr atomic ratio of 1:4 shows the highest  $\text{CO}_2$  conversion of 26.7% and high  $\text{C}_2^- - \text{C}_4^-$  selectivity of 88.8% in hydrocarbon. Moreover, the CO selectivity decreases to the minimum value of 52.4% at the same time, suggesting the introduction of optimized Ga to  $\text{ZrO}_2$  not only improve the  $\text{CO}_2$  conversion, but also obviously inhibit the CO formation, the obtained  $\text{C}_2^- - \text{C}_4^-$  yield is as high as 11.3%, which outperforms the previously reported results as shown in Table S1. Moreover, it is found that the selectivity of  $\text{C}_2^- - \text{C}_4^-$  obviously decreases to 75.9% as Ga:Zr ratio reaches 4:1, suggesting that the high content of Ga leads to excessive hydrogenation of light olefin. The catalytic performance can be further enhanced by adjusting the reaction conditions. Fig. 1b and Fig. 1c show that as the temperature increases or GHSV decreases, both  $\text{CO}_2$  conversion and  $\text{C}_2^- - \text{C}_4^-$  yield gradually boost, while the  $\text{C}_2^- - \text{C}_4^-$  selectivity slightly reduces. However, both the reaction temperature and GHSV show little effect on CO selectivity, even at high temperature of  $400^\circ\text{C}$  or  $410^\circ\text{C}$ , the CO selectivity keep about 52–54%. As comparison, for other typically bifunctional catalysts reported in the previous literature, such high reaction temperature leads to the very high CO selectivity of 65–85% (Table S1). The catalytic stability result for Ga:Zr(1:4)/SAPO-34 catalyst is shown in Fig. 1d. After the induction period, the  $\text{CO}_2$

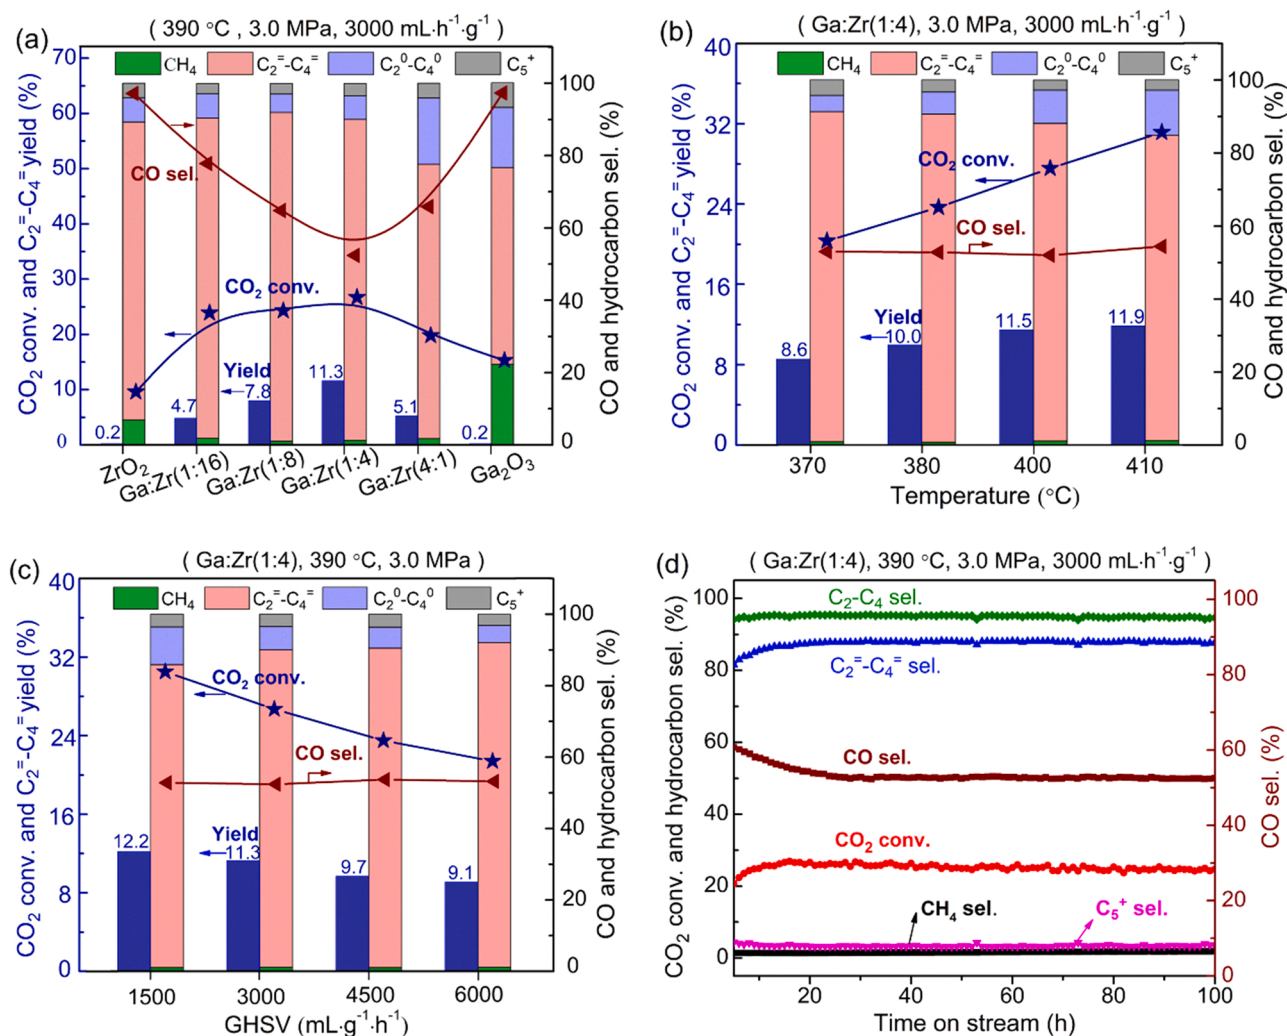

Fig. 1. Catalytic performance of CO<sub>2</sub> hydrogenation into light olefin over GaZrO<sub>x</sub> combined with SAPO-34.

conversion, C<sub>2</sub>=-C<sub>4</sub>= selectivity and CO selectivity kept stable at around 26%, 88% and 52%, respectively. No obvious deactivation is observed after a reaction time for 100 h, suggesting a potential for industrial application.

### 3.2. Structure and morphology analysis

To investigate the structure of GaZrO<sub>x</sub> with various Ga:Zr atomic ratios, XRD patterns are performed and displayed in Fig. 2a. The sole ZrO<sub>2</sub> shows the characteristic diffraction peaks at 2θ of 30.3°, 35.3°, 50.6°, 60.2°, 63.0°, and 74.5°, corresponding to tetragonal ZrO<sub>2</sub> (*t*-ZrO<sub>2</sub>, PDF#50-1089), and the very weak diffraction peaks at 24.0°, 28.2°, 31.4° and 40.7° are attributed to monoclinic ZrO<sub>2</sub> (*m*-ZrO<sub>2</sub>, PDF#37-1484). After the introduction of small amount of Ga, the diffraction peaks corresponding to *m*-ZrO<sub>2</sub> disappear, and the *t*-ZrO<sub>2</sub> phase of Ga:Zr(1:16) and Ga:Zr(1:8) shifts to higher angles, compared with the sole ZrO<sub>2</sub> as shown in Fig. S3; Moreover, no crystalline phase corresponding to Ga<sub>2</sub>O<sub>3</sub> is detected. The results confirm that Ga incorporated into ZrO<sub>2</sub> crystal lattice and thus shrank the ZrO<sub>2</sub> crystal spacing, which is attributed to the larger atomic radius of Zr<sup>4+</sup> (0.072 nm) than that of Ga<sup>3+</sup> (0.062 nm). It is interesting to find that Ga:Zr(1:4) exhibits amorphous structure, suggesting that the introduction of certain amount of Ga into ZrO<sub>2</sub> form a highly dispersed Zr and Ga species. Ga:Zr(4:1) exhibits the characteristic peaks of α-Ga<sub>2</sub>O<sub>3</sub> (PDF#06-0503), which is similar to that of sole Ga<sub>2</sub>O<sub>3</sub>. No crystalline phase corresponding to *t*-ZrO<sub>2</sub> or *m*-ZrO<sub>2</sub> is detected.

Raman spectra of metal oxides are shown in Fig. 2b. For sole ZrO<sub>2</sub>, the characteristic peaks corresponding to *t*-ZrO<sub>2</sub> at 148, 268, 316, 461, and 644 cm<sup>-1</sup> as well as corresponding to *m*-ZrO<sub>2</sub> at 178, 189, and 382 cm<sup>-1</sup> are presented, indicating that *t*-ZrO<sub>2</sub> and *m*-ZrO<sub>2</sub> are co-existed in sole ZrO<sub>2</sub> sample, and *t*-ZrO<sub>2</sub> is the dominant phase [33]. For binary oxides Ga:Zr(1:16) and Ga:Zr(1:8), the peaks belonging to *m*-ZrO<sub>2</sub> disappear, and the peaks intensity for *t*-ZrO<sub>2</sub> decrease as the Ga:Zr atomic ratio increases. Interestingly, Ga:Zr(1:4) displays no obvious peaks, suggesting the high dispersion of Zr and Ga species in GaZrO<sub>x</sub>. Further increasing the Ga:Zr atomic ratio, the characteristic peaks corresponding to α-Ga<sub>2</sub>O<sub>3</sub> at 218, 287, 433, 570, 648, and 709 cm<sup>-1</sup> are observed [34], similar to that of sole Ga<sub>2</sub>O<sub>3</sub> sample. These results are consistent with XRD analysis.

The molecular specificity and surface sensitivity TOF-SIMS is used to further determine to molecular structure and surface composition in GaZrO<sub>x</sub> [35], Fig. 2c shows the partial negative TOF-SIMS spectra result in Ga:Zr(1:4), the ions of GaZrO<sup>-</sup> (*m/z* = 176.8), GaZrO<sub>2</sub><sup>-</sup> (*m/z* = 192.8), GaZrO<sub>3</sub><sup>-</sup> (*m/z* = 208.8), GaZrO<sub>4</sub><sup>-</sup> (*m/z* = 224.8), GaZrO<sub>5</sub><sup>-</sup> (*m/z* = 240.8) are presented, this result provides strong evidence that the Ga-O-Zr bridges existed in GaZrO<sub>x</sub> [20], confirming the introduction of Ga into ZrO<sub>2</sub> formed the solid solution structure with the cation substitution.

To study the morphology and crystallite transformation of metal oxides, TEM and HR-TEM images of sole ZrO<sub>2</sub>, Ga:Zr(1:8), Ga:Zr(1:4), Ga:Zr(4:1), and Ga<sub>2</sub>O<sub>3</sub> are performed and shown in Fig. 3. As shown in Fig. 3a, sole ZrO<sub>2</sub> shows irregular agglomeration of nanoparticles. After the introduction of Ga and increasing the Ga:Zr atomic ratio, the

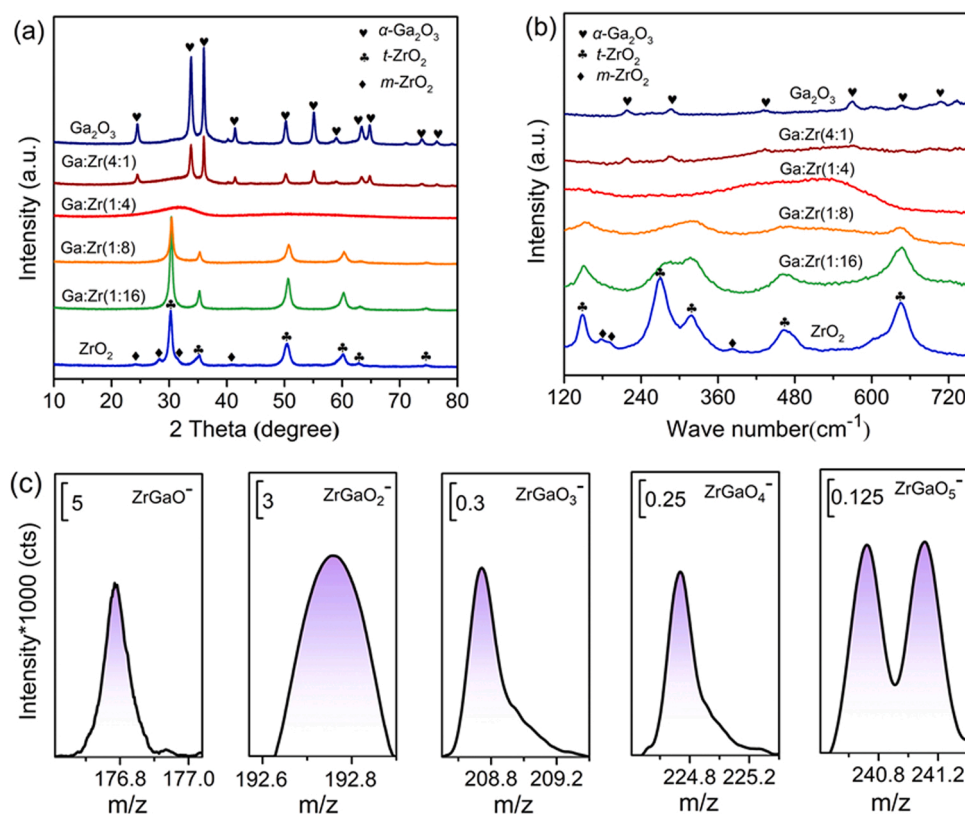

Fig. 2. (a) XRD patterns, (b) Raman spectra of GaZrO<sub>x</sub> with various Ga:Zr atomic ratios, and (c) Partial negative TOF-SIMS spectra of the GaZrO<sub>x</sub> with Ga:Zr atomic ratio of 1:4.

morphology of GaZrO<sub>x</sub> gradually shifts to rod-like morphology, as shown in Fig. 3b-d. In particular, Ga:Zr(4:1) in Fig. 3d with more content of Ga displays the similar particles morphology to that of sole Ga<sub>2</sub>O<sub>3</sub> (Fig. 3e), which exhibits a regular monodispersed rod-like morphology. The inset HR-TEM image of sole ZrO<sub>2</sub> shows a well-defined lattice fringe of 0.299 nm, corresponding to *t*-ZrO<sub>2</sub>(011). The introduction of Ga shrank the lattice fringe of Ga:Zr(1:8) to 0.291 nm, suggesting that Ga<sup>3+</sup> is incorporated into the lattice of ZrO<sub>2</sub>. Ga:Zr(1:4) exhibits no lattice fringes, which is probably due to the high mutual solubility of Zr and Ga species. Ga:Zr(4:1) shows the lattice fringe of 0.370 nm, which is similar to that of sole Ga<sub>2</sub>O<sub>3</sub> (0.371 nm), corresponding to  $\alpha$ -Ga<sub>2</sub>O<sub>3</sub> (012). The HRTEM-EDS images in Fig. 3f demonstrate that the elements of Zr, Ga and O are uniformly dispersed in Ga:Zr (1:4) oxide sample, consistent with XRD and Raman analyses.

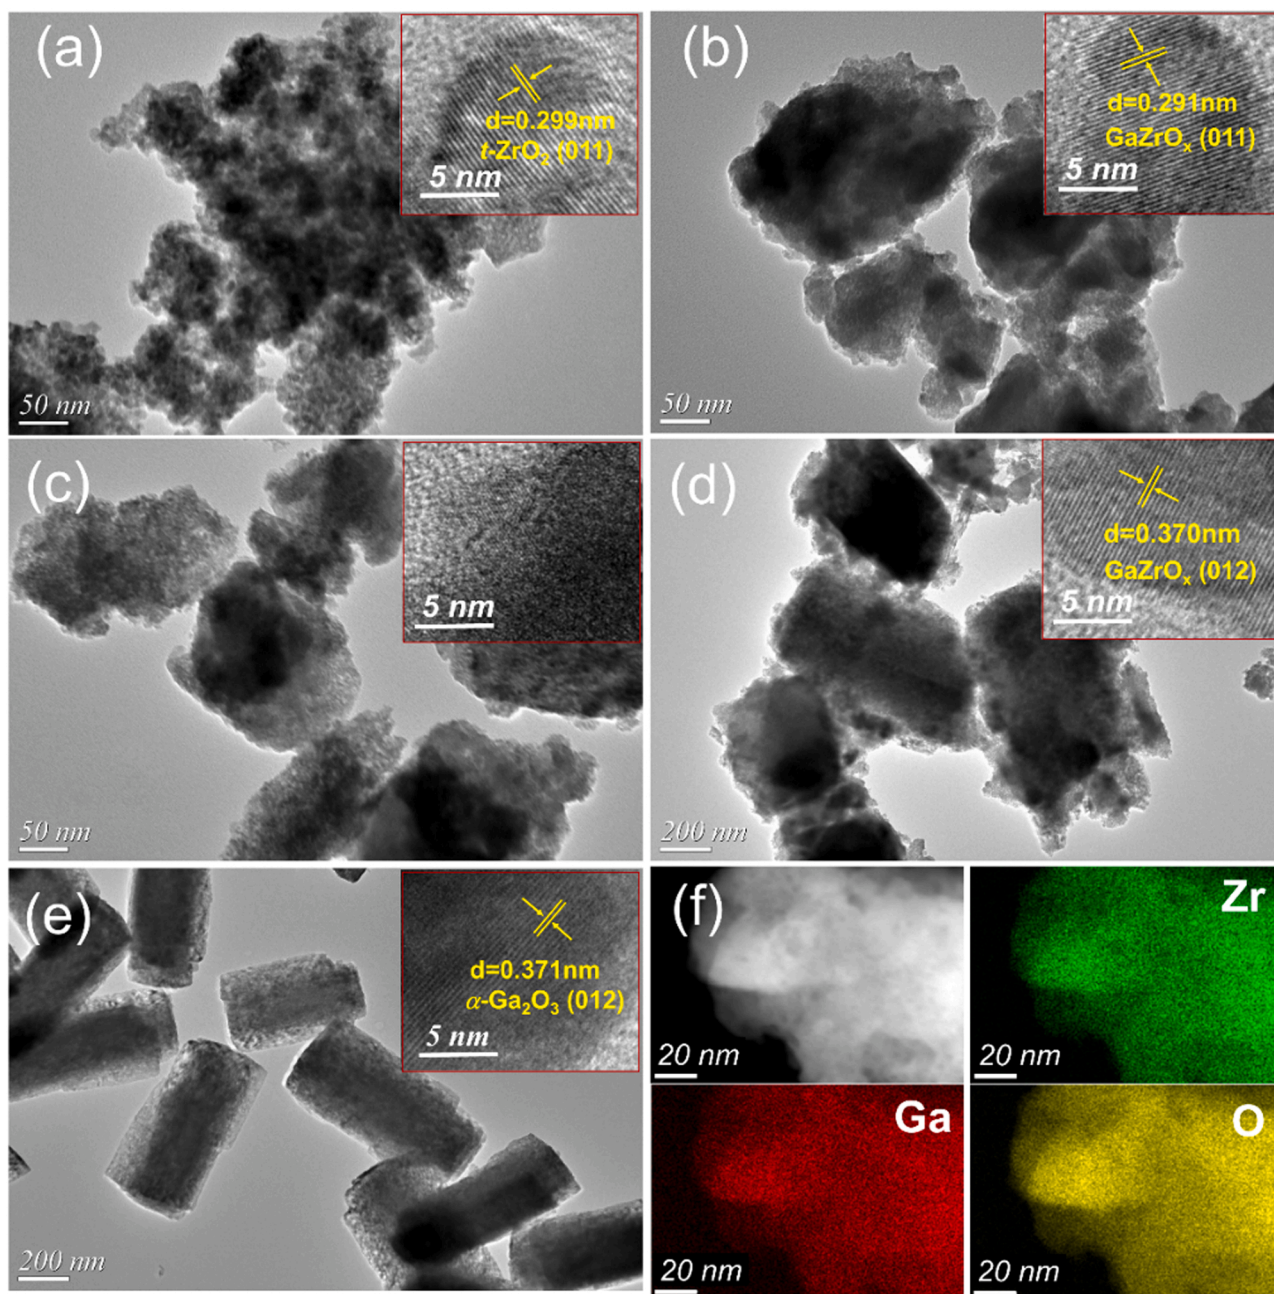

### 3.3. Surface property analysis

XPS spectra results of Ga 2p<sub>3/2</sub> in metal oxides are shown in Fig. 4a, for sole Ga<sub>2</sub>O<sub>3</sub>, the binding energies of Ga 2p<sub>3/2</sub> at 1118.7 eV is assigned to the bonding of Ga-OH species in Ga(OH)<sub>3</sub> [36], which produced from the remnants of growth precursor. The binding energies at 1117.3 eV is attributed to the Ga<sup>3+</sup> species in Ga<sub>2</sub>O<sub>3</sub> [37], it is found the binding energies for Ga<sup>3+</sup> species in GaZrO<sub>x</sub> is higher than that of Ga<sub>2</sub>O<sub>3</sub>, the variation tendency of Ga 2p<sub>3/2</sub> indicates that the electronic property of the Ga site is modified by the adjacent Zr site, caused by the incorporation of Ga into ZrO<sub>2</sub> lattice. The surface oxygen vacancy concentration in GaZrO<sub>x</sub> is further studied by O 1s spectra. Three types of O species are observed in O 1s spectra as shown in Fig. 4b. The peaks centered at the binding energies of 529.5–530.5 eV are attributed to lattice oxygen (O<sub>L</sub>), the peaks occurred at binding energies of 530.5–531.5 eV is associated with oxygen atoms next to surface oxygen vacancy (O<sub>V</sub>), and the peaks located at 531.5–532.5 eV are attributed to hydroxyl group (O<sub>OH</sub>) [13, 38, 39], the concentrations of these surface oxygen species are listed in

Table S2, as the Ga:Zr atomic ratio increases, the binding energy of O 1s shifts towards higher binding energy, which is due to the formation of Ga–O–Zr structure. Furthermore, it is found that the concentration of O<sub>V</sub> firstly increases and then decreases as the Ga:Zr atomic ratio increases, Ga:Zr(1:4) oxide shows the highest O<sub>V</sub> concentration of 32.6%, confirming the introduction of an optimal amount of Ga into ZrO<sub>2</sub> lattice benefits the formation of large amounts of surface oxygen vacancy. EPR is further used to characterize the O<sub>V</sub> concentration in the bulk and surface of metal oxides [40], it is found the EPR signal at *g* = 2.002, which is presented due to the unpaired electrons trapped on O<sub>V</sub>, firstly increases and then decreases as the Ga:Zr atomic ratio increases, Ga:Zr (1:4) oxide shows the highest O<sub>V</sub> concentration in comparison to the other samples, consistent with the XPS result.

The adsorption ability of CO<sub>2</sub> for metal oxides is examined by CO<sub>2</sub>-TPD. The profiles are shown in Fig. 5. Two distinct desorption regions in the range of 50–150 °C and 280–360 °C are observed and denoted as peak  $\alpha$  and  $\beta$ . The low-temperature CO<sub>2</sub> desorption peaks centered at ca. 90 °C are attributed to the physical adsorption of CO<sub>2</sub> on GaZrO<sub>x</sub> oxides surface. While the desorption peaks at high-temperature are ascribed to the strong chemisorption sites [13, 14]. The amounts of desorbed CO<sub>2</sub> for peak  $\beta$  listed in Table S3 follow the sequence: Ga:Zr(1:4) > Ga:Zr(1:8) > Ga:Zr(1:16) > ZrO<sub>2</sub> > Ga:Zr(4:1) > Ga<sub>2</sub>O<sub>3</sub>. To evaluate the dissociation ability of H<sub>2</sub> of metal oxides, the hydrogenation of ethylene over metal oxides is selected as a probe reaction to represent H<sub>2</sub> dissociation ability. The results are shown in Fig. S4. After normalizing the conversion of C<sub>2</sub>H<sub>4</sub>, the sole ZrO<sub>2</sub> exhibits the lowest H<sub>2</sub> dissociation ability (6.9). The H<sub>2</sub> dissociation ability enhances after the introduction of Ga into ZrO<sub>2</sub> and linearly increases with the increasing of Ga:Zr atomic ratio. In addition, the H<sub>2</sub> dissociation ability is not related to the specific surface area as shown in Table S4. Thus, it is concluded that Ga species is mainly responsible for H<sub>2</sub> activation. Increasing Ga content leads to an obvious increase of H<sub>2</sub> dissociation ability.

Fig. 6 shows the relationship between the catalytic performance and

**Fig. 3.** TEM images with inset HR-TEM images of metal oxides. (a)  $\text{ZrO}_2$ , (b)  $\text{Ga:Zr}(1:8)$ , (c)  $\text{Ga:Zr}(1:4)$ , (d)  $\text{Ga:Zr}(4:1)$ , (e)  $\text{Ga}_2\text{O}_3$ , and (f) EDS-mapping diagram of  $\text{Ga:Zr}(1:4)$ .

structure. As shown in Fig. 6a, as the Ga:Zr atomic ratio increases, the surface  $\text{O}_V$  concentration firstly increases and then decreases, while the  $\text{H}_2$  dissociation ability gradually increases.  $\text{Ga:Zr}(1:4)$  exhibits the highest  $\text{C}_2^--\text{C}_4^=$  yield among the investigated samples, which possesses the highest surface  $\text{O}_V$  content with moderate  $\text{H}_2$  dissociation ability. As shown in Fig. 6b, it is found that the  $\text{CO}_2$  desorption amount shows obvious linear correlation with the surface  $\text{O}_V$  content, indicating that the presence of surface  $\text{O}_V$  of  $\text{GaZrO}_x$  oxides facilitate the adsorption and activation of  $\text{CO}_2$ . Moreover, the linear correlation between  $\text{CO}_2$  conversion and surface  $\text{O}_V$  content also confirms that the surface  $\text{O}_V$  serving as the active site promotes the conversion of  $\text{CO}_2$ , similar finding was also reported to prove that  $\text{O}_V$  is the active site for  $\text{CO}_2$  adsorption and activation over  $\text{ZnO-ZrO}_2$  oxide, and the formation rate of methanol/DME intermediate is dominated by the total amount of  $\text{O}_V$  [41]. As shown in Fig. 6c, it is found that increasing a certain  $\text{H}_2$  dissociation

ability ( $<50$ ) do not obviously influence the O/P ratio, it is inferred that the formation rate of “dissociated  $\text{H}_2$ ” is well matched with the “active  $\text{CO}_2$ ” produced by surface  $\text{O}_V$ , thus avoiding the second hydrogenation of olefin. While the strong  $\text{H}_2$  dissociation ability ( $>50$ ) makes the “dissociated  $\text{H}_2$ ” is excessive, leading to the more paraffin formation. As shown in Fig. 6d, increasing  $\text{H}_2$  dissociation ability in  $\text{GaZrO}_x$  leads to the total hydrocarbon selectivity firstly increases and then decreases, while the  $\text{CO}$  selectivity is inverse, which indicates that the moderate  $\text{H}_2$  dissociation ability produced by incorporation optimal Ga is more favorable for hydrocarbon products formation. Above analysis suggests that both surface  $\text{O}_V$  content and  $\text{H}_2$  dissociation ability created by synergistic effect of Ga and Zr in  $\text{GaZrO}_x$  dominates the catalytic performance. The high surface  $\text{O}_V$  content (32.6%) with moderate  $\text{H}_2$  dissociation ability (56.9) over  $\text{Ga:Zr}(1:4)$  oxide not only improves the  $\text{CO}_2$  conversion, but also obviously inhibits the excessive hydrogenation

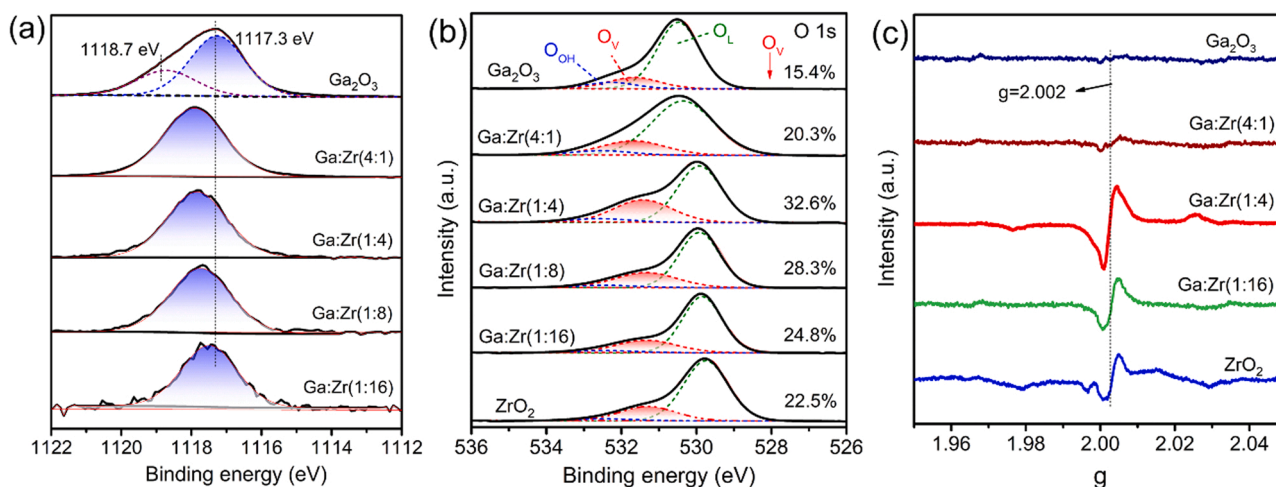

Fig. 4. (a) Ga 2p XPS spectra, (b) O 1s XPS spectra, and (c) EPR spectra of GaZrO<sub>x</sub> with various Ga:Zr atomic ratios.

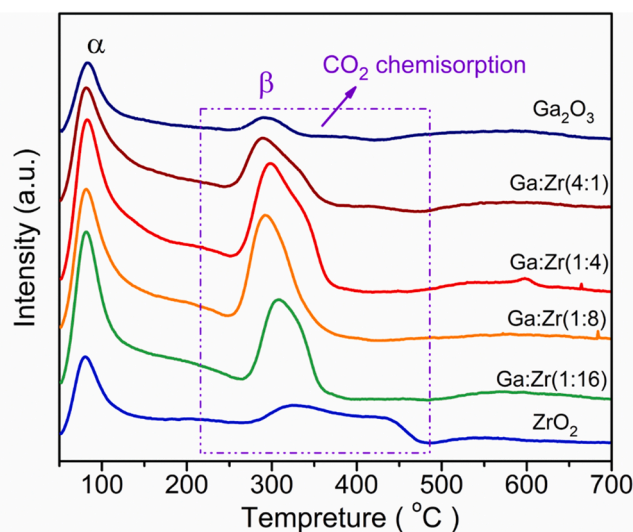

Fig. 5. CO<sub>2</sub>-TPD profiles of GaZrO<sub>x</sub> with various Ga:Zr atomic ratios.

of C<sub>2</sub>=C<sub>4</sub>= and RWGS reaction, in turn boosting the yield of C<sub>2</sub>=C<sub>4</sub>=.

The in-situ DRIFT spectra of metal oxides in H<sub>2</sub> flow under 390 °C are shown in Fig. 7a. The bands at 3745 cm<sup>-1</sup> and 3668 cm<sup>-1</sup> are assigned to the terminal hydroxyl and bridged hydroxyl, respectively [42]. All the metal oxides, except the sole Ga<sub>2</sub>O<sub>3</sub>, exhibit the signals for the terminal hydroxyl and bridged hydroxyl. For the sole Ga<sub>2</sub>O<sub>3</sub>, only the bridged hydroxyl appears. Interestingly, a new band presents at 1988 cm<sup>-1</sup>, produced from H<sub>2</sub> dissociation on the surface of Ga<sub>2</sub>O<sub>3</sub>, is attributed to Ga-H species [29], indicating that the H<sub>2</sub> dissociates on the Ga-O site, producing the O-H and Ga-H group, which is consistent with the previous reports [29,43]. Moreover, the increase of Ga:Zr atomic ratio enhances the intensity of Ga-H band, which is due to the high dissociation ability of Ga species.

To further distinguish the key surface intermediates over Ga:Zr(1:4) oxide, the adsorption of H<sub>2</sub> for CO<sub>2</sub>-pretreated Ga:Zr(1:4) oxide at different time is shown in Fig. 7b. After the adsorption of time for 1 min, the peaks ascribed to bidentate formate (bi-HCOO\*) at 2968, 2879, 1587, 1386, and 1366 cm<sup>-1</sup> appear [23,27,44,45]. As the adsorption time increases to 3 min, new apparent peaks at 2933, 2825, 1139 and 1037 cm<sup>-1</sup> related to methoxide group (CH<sub>3</sub>O\*) are observed and gradually intensified [44,46]. The results indicate that the hydrogenation of CO<sub>2</sub> generates the HCOO\*, then HCOO\* converts to CH<sub>3</sub>O\*, suggesting that CH<sub>3</sub>O\* is more likely the key intermediate during the

CO<sub>2</sub> hydrogenation process. Subsequently, the Ga:Zr(1:4) oxide was exposed to mixture gas (CO<sub>2</sub> + H<sub>2</sub>) at different temperatures, it is found that the peaks ascribed to CH<sub>3</sub>O\* species gradually decrease as the temperature increases, owing to the thermodynamic effect that inhibits the production of CH<sub>3</sub>O\* species at high temperature, but still clearly observed even up to 360 °C and 390 °C, suggesting that Ga:Zr(1:4) oxide can produce and stabilize the CH<sub>3</sub>O\* at high temperature. Upon combination with SAPO-34, as shown in Fig. S5, however, both signal for HCOO\* and CH<sub>3</sub>O\* are much weaker, and the new ν(C=C) peaks at 1300 – 1000 cm<sup>-1</sup> are observed at high temperature [47], implying that the CH<sub>3</sub>O\* converts to olefin in the presence of SAPO-34.

For comparison, the DRIFT spectra of sole ZrO<sub>2</sub> and Ga<sub>2</sub>O<sub>3</sub>, treated by CO<sub>2</sub> + H<sub>2</sub> flow at different temperatures are displayed in Fig. 7c and Fig. 7d, and other GaZrO<sub>x</sub> with Ga:Zr atomic ratio of 1:16, 1:8, and 4:1 are shown in Fig. S6. The sole ZrO<sub>2</sub> shows that only exhibits the strong signal for HCOO\* (2965, 2878, 1585, 1385, 1366) at 240–420 °C, and no signal for CH<sub>3</sub>O\* is observed (Fig. 7c), the results indicate that the formation of HCOO\* species via CO<sub>2</sub> hydrogenation is a facile step, which is not influenced by weak H<sub>2</sub> dissociation ability of ZrO<sub>2</sub>. While the hydrogenation of HCOO\* to form CH<sub>3</sub>O\* is dominated by H<sub>2</sub> dissociation of metal oxide. It is found the introduction of Ga can obviously boost the conversion of HCOO\* to CH<sub>3</sub>O\* (Fig. S6), which is due to the introduction of Ga accelerate the H<sub>2</sub> dissociation, confirming the vital role of Ga species in the conversion HCOO\* to form CH<sub>3</sub>O\*; however, the GaZrO<sub>x</sub> with excessive Ga leads to the obvious decrease the intensity of HCOO\* at high temperature (Fig. S6c). For sole Ga<sub>2</sub>O<sub>3</sub> as shown in Fig. 7d, the signals for both HCOO\* (2973, 2889, 1599, 1385, 1368 cm<sup>-1</sup>) and CH<sub>3</sub>O\* (2938, 2832 cm<sup>-1</sup>) are detected between the temperature of 270 °C and 360 °C. However, the intensity of these peaks are extremely weak, especially at high temperature (>360 °C), implying that the formation of the HCOO\* and CH<sub>3</sub>O\* over sole Ga<sub>2</sub>O<sub>3</sub> or GaZrO<sub>x</sub> at high Ga content are obviously limited at high temperature.

Interestingly, it is found that the peak positions of HCOO\* species for all the GaZrO<sub>x</sub> oxides are well accordance with the ZrO<sub>2</sub>, and the peak positions of both HCOO\* and CH<sub>3</sub>O\* in GaZrO<sub>x</sub> oxides are much lower than Ga<sub>2</sub>O<sub>3</sub> (Fig. 7, Fig. S6), it is reasonable to deduce that the oxygen vacancy at Zr site in GaZrO<sub>x</sub> is mainly responsible for CO<sub>2</sub> adsorption, activation, while Ga sites provide the essential hydrogenation sites, the moderate H<sub>2</sub> dissociation ability produced by incorporation optimal Ga boosts CO<sub>2</sub> hydrogenation to CH<sub>3</sub>O\* intermediate at high temperature.

#### 3.4. DFT calculations

To illustrate above experimental results and gain a deeper insight of the CO<sub>2</sub>/H<sub>2</sub> adsorption, activation, and the hydrogenation mechanism

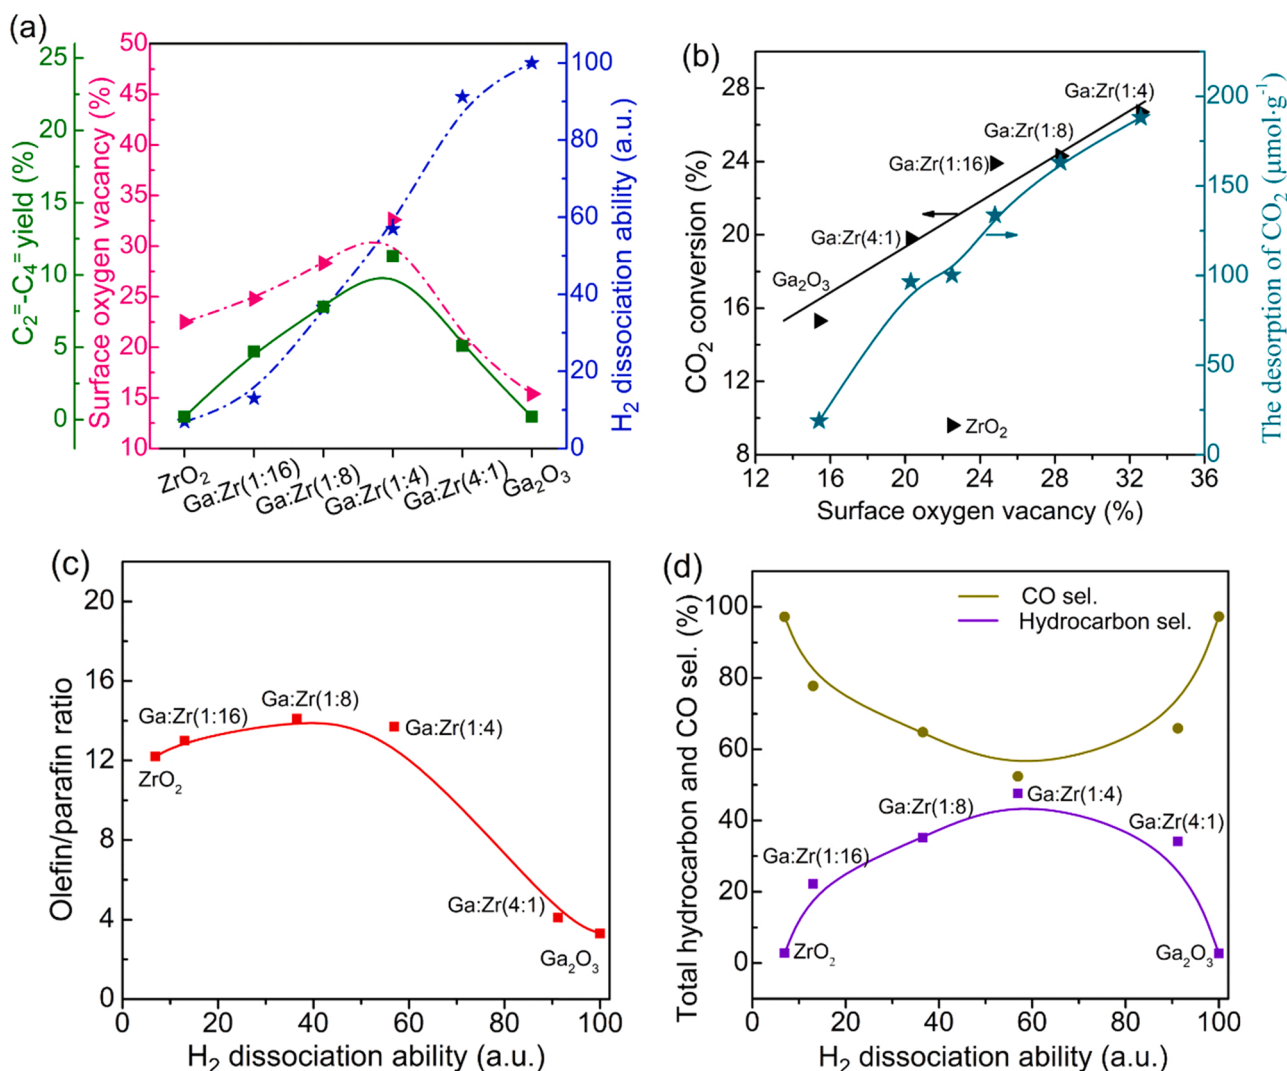

Fig. 6. Relationship between catalyst activity, CO<sub>2</sub> desorption amount, and surface oxygen vacancy content, H<sub>2</sub> dissociation ability. Reaction condition: 390 °C, 3.0 MPa, GHSV = 3000 mL·h<sup>-1</sup>·g<sup>-1</sup>.

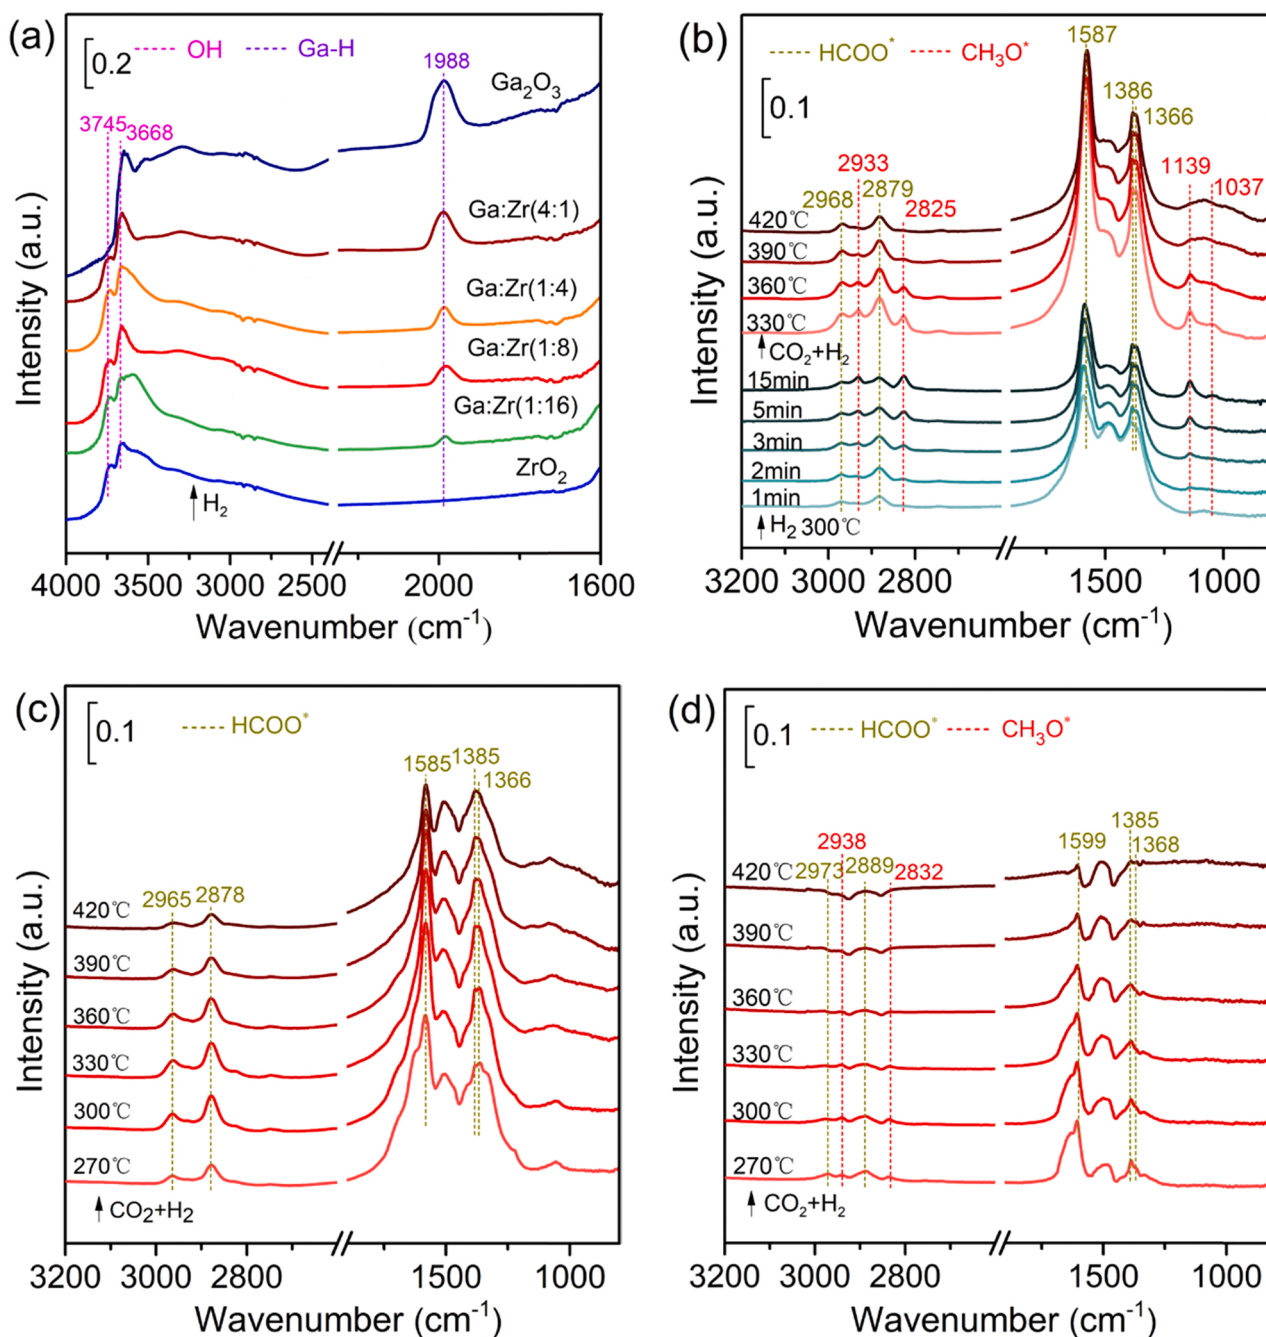

over GaZrO<sub>x</sub> oxide, DFT calculations are performed by considering the O<sub>V</sub>-ZrO<sub>2</sub>(101), O<sub>V</sub>-GaZrO<sub>x</sub>(101) and O<sub>V</sub>-Ga<sub>2</sub>O<sub>3</sub>(012) surface model (Fig. S7).

The activation of CO<sub>2</sub>/H<sub>2</sub> over O<sub>V</sub>-GaZrO<sub>x</sub>(101) is shown in Fig. 8. the CO<sub>2</sub> chemisorption at the O<sub>V</sub> results in the formation of C-Zr and O-Zr bond with the adsorption energy of -26.2 kJ·mol<sup>-1</sup>, the C-O bond lengths (C-O<sub>1</sub> and C-O<sub>2</sub>) of 1.213 and 1.266 Å and the bent O-C-O angle of 138.180° (Fig. 8a), notably, compared to the perfect GaZrO<sub>x</sub>(101), DFT result suggests the presence of oxygen vacancy promotes CO<sub>2</sub> adsorption and activation, which is consistent with the experimental and characterized results (Fig. S8). The electronic property of adsorbed CO<sub>2</sub> on O<sub>V</sub>-GaZrO<sub>x</sub>(101) is examined by differential charge density and Bader charge analysis, it is found that the oxidation state of C atom in CO<sub>2</sub> decreased, the C atom of CO<sub>2</sub> loses 1.44 |e|, both O<sub>1</sub> and O<sub>2</sub> atoms of CO<sub>2</sub> carry extra 1.12 and 0.97 |e|, in which the electron depletion region appears around the C atom, and the asymmetric electron enrichment area are around the adjacent O atoms. Confirming that CO<sub>2</sub> activation is attributed to the electrons trapped in the O<sub>V</sub> site.

For the adsorption of H<sub>2</sub>, as shown in Fig. 8b, H<sub>2</sub> can spontaneously dissociate into two H atoms, which are adsorbed at the Ga and O sites on the O<sub>V</sub>-GaZrO<sub>x</sub>(101), two H atoms are elongated to 2.773 Å. For comparison, H<sub>2</sub> is typically physisorbed at the top-Zr site on O<sub>V</sub>-ZrO<sub>2</sub>(101) with the H-H bond length of 0.755 Å (Fig. S9a), while H<sub>2</sub> can also

spontaneously dissociate into two H atoms, which are adsorbed at two Ga sites on O<sub>V</sub>-Ga<sub>2</sub>O<sub>3</sub>(012), two H atoms are elongated to 3.085 Å (Fig. S9b). Which indicated that ZrO<sub>2</sub> has weak H<sub>2</sub> dissociation ability, the introduction of Ga to ZrO<sub>2</sub> obviously enhances H<sub>2</sub> dissociation ability, which well confirms our experimental and characterized results. The differential charge density and Bader charge analysis are carried out for two adsorbed H atoms from H<sub>2</sub> dissociative adsorption on O<sub>V</sub>-GaZrO<sub>x</sub>(101). H adsorbed at the O site loses 0.68 |e| and become positively charged, while H adsorbed at the Ga site carry extra 0.34 |e| and become negatively charged. Thus, the Ga-O bridge site can act as the active center to produce an H<sup>δ-</sup> located at the Ga site and an H<sup>δ+</sup> located at the O site, which is attributed to the local charge polarization along the Ga-O bond.

Two major reaction pathways of CO<sub>2</sub> hydrogenation, the formate and RWGS pathways, are considered over O<sub>V</sub>-GaZrO<sub>x</sub>(101) model, as shown in Fig. 9a. The corresponding structures involving in CO<sub>2</sub> hydrogenation through formate pathway are presented in Fig. 9b. The calculated activation barrier (G<sub>a</sub>) and reaction energy (ΔG) are listed in Table S6. In the formate pathway, the adsorbed CO<sub>2</sub> reacts with the nearby Ga-H<sup>δ-</sup> to form HCOO\*, which has the activation free energy of 13.6 kJ·mol<sup>-1</sup>, and it is strongly exothermic by -124.4 kJ·mol<sup>-1</sup>. Suggesting that the reaction of adsorbed CO<sub>2</sub> with dissociated H\* to form HCOO\* species is energetically very favorable, which is consistent with the in-situ DRIFT

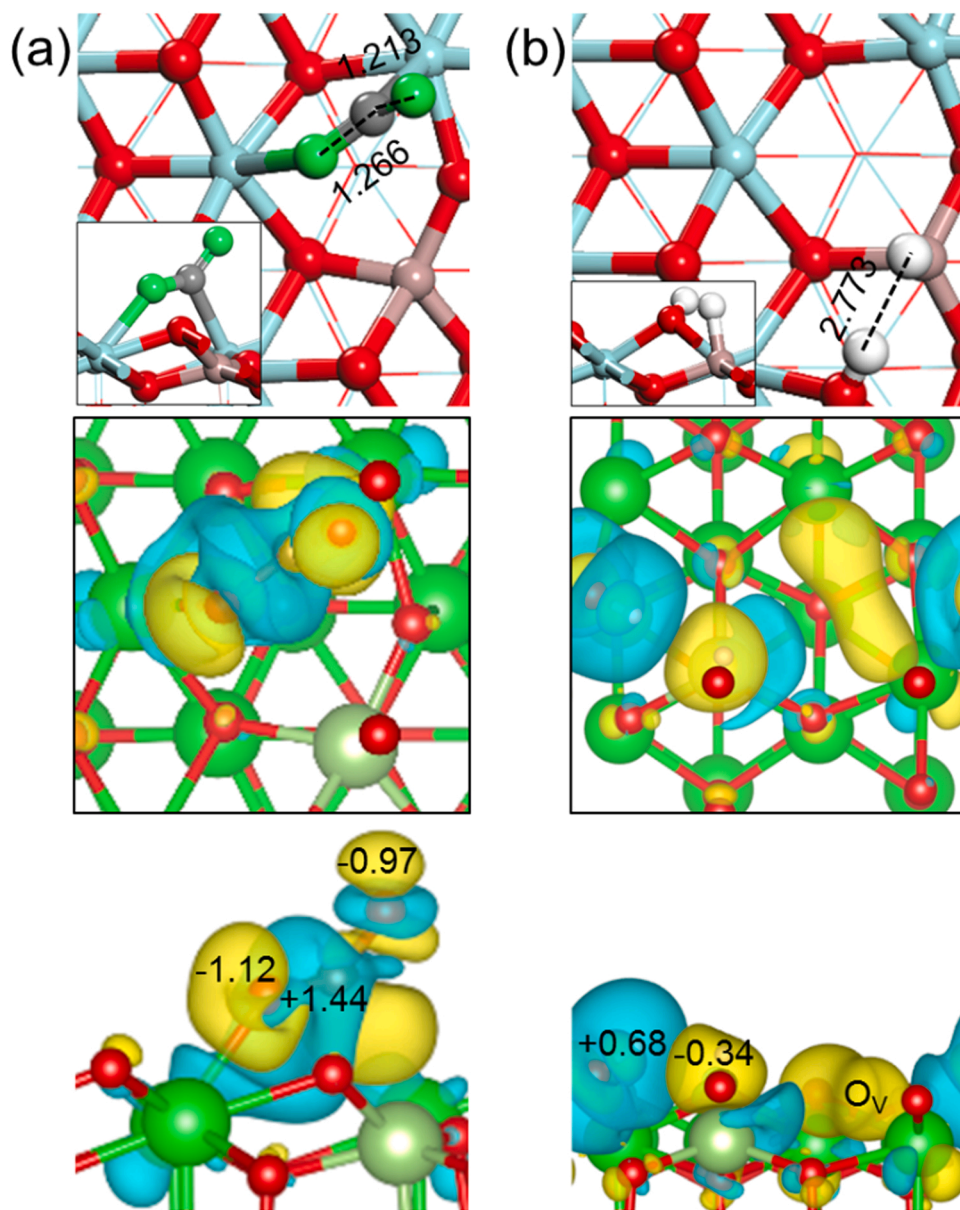

**Fig. 7.** In-situ DRIFT spectra. (a) GaZrO<sub>x</sub> with various Ga:Zr atomic ratios treated by H<sub>2</sub> flow at 390 °C, (b) CO<sub>2</sub>-pretreated Ga:Zr(1:4) oxide treated by H<sub>2</sub> flow at 300 °C and subsequent switched to CO<sub>2</sub> + H<sub>2</sub> at different temperatures, (c) sole ZrO<sub>2</sub> and (d) sole Ga<sub>2</sub>O<sub>3</sub> treated by CO<sub>2</sub> + H<sub>2</sub> flow at different temperatures.

results. HCOO\* hydrogenation to H<sub>2</sub>COO\* has the activation free energy of 49.2 kJ·mol<sup>-1</sup>, and it is endothermic by 37.2 kJ·mol<sup>-1</sup>. Then, H<sub>2</sub>COO\* hydrogenation to H<sub>2</sub>COOH\* has a small activation free energy of 10.6 kJ·mol<sup>-1</sup> with the reaction energy of -44.9 kJ·mol<sup>-1</sup>. Subsequently, the C-O bond cleavage of H<sub>2</sub>COOH\* can produce CH<sub>2</sub>O\* and OH\* adsorbed at the bridge Zr-Zr and Ga sites, respectively, which is identified as the rate-determining step of the overall reaction, correspondingly, this reaction has a higher activation free energy of 86.7 kJ·mol<sup>-1</sup>, and it is exothermic by 55.9 kJ·mol<sup>-1</sup>. Further, CH<sub>2</sub>O\* hydrogenation to CH<sub>3</sub>O\* is energetically favorable with the activation and reaction free energies of 21.6 and -72.1 kJ·mol<sup>-1</sup>, respectively. Finally, CH<sub>3</sub>OH formed by the hydrogenation of CH<sub>3</sub>O\* - with activation and reaction free energies of 79.3 and 79.2 kJ·mol<sup>-1</sup>. Notably, it is found that CH<sub>3</sub>OH cannot be stably adsorbed on the surface

Ov-GaZrO<sub>x</sub>(101) due to its much easier dissociation into CH<sub>3</sub>O\* and H\* species in kinetics (Fig. S10). It is concluded that CH<sub>3</sub>O\* is more likely the reaction intermediate linked the metal oxide and SAPO-34.

In the RWGS pathway, CO<sub>2</sub> hydrogenation to form *trans*-COOH\* has the activation and reaction free energies of 110.8 and 7.9 kJ·mol<sup>-1</sup>, respectively, which is kinetically and thermodynamically unfavorable compared to HCOO\* formation, meanwhile, *trans*-COOH\* formation is the rate-determining step of the overall reaction. Then, *trans*-COOH\* is isomerized into *cis*-COOH\* with the activation and reaction free energies of 27.7 and 26.6 kJ·mol<sup>-1</sup>, respectively. CO\* can be produced by the dissociation of *cis*-COOH\* with the activation and reaction free energies of 28.1 and -43.0 kJ·mol<sup>-1</sup>, respectively. The weakly bonded CO\* prefers to desorb from the metal oxide surface instead of further hydrogenation, making the CO as the main product. Hence, it can be

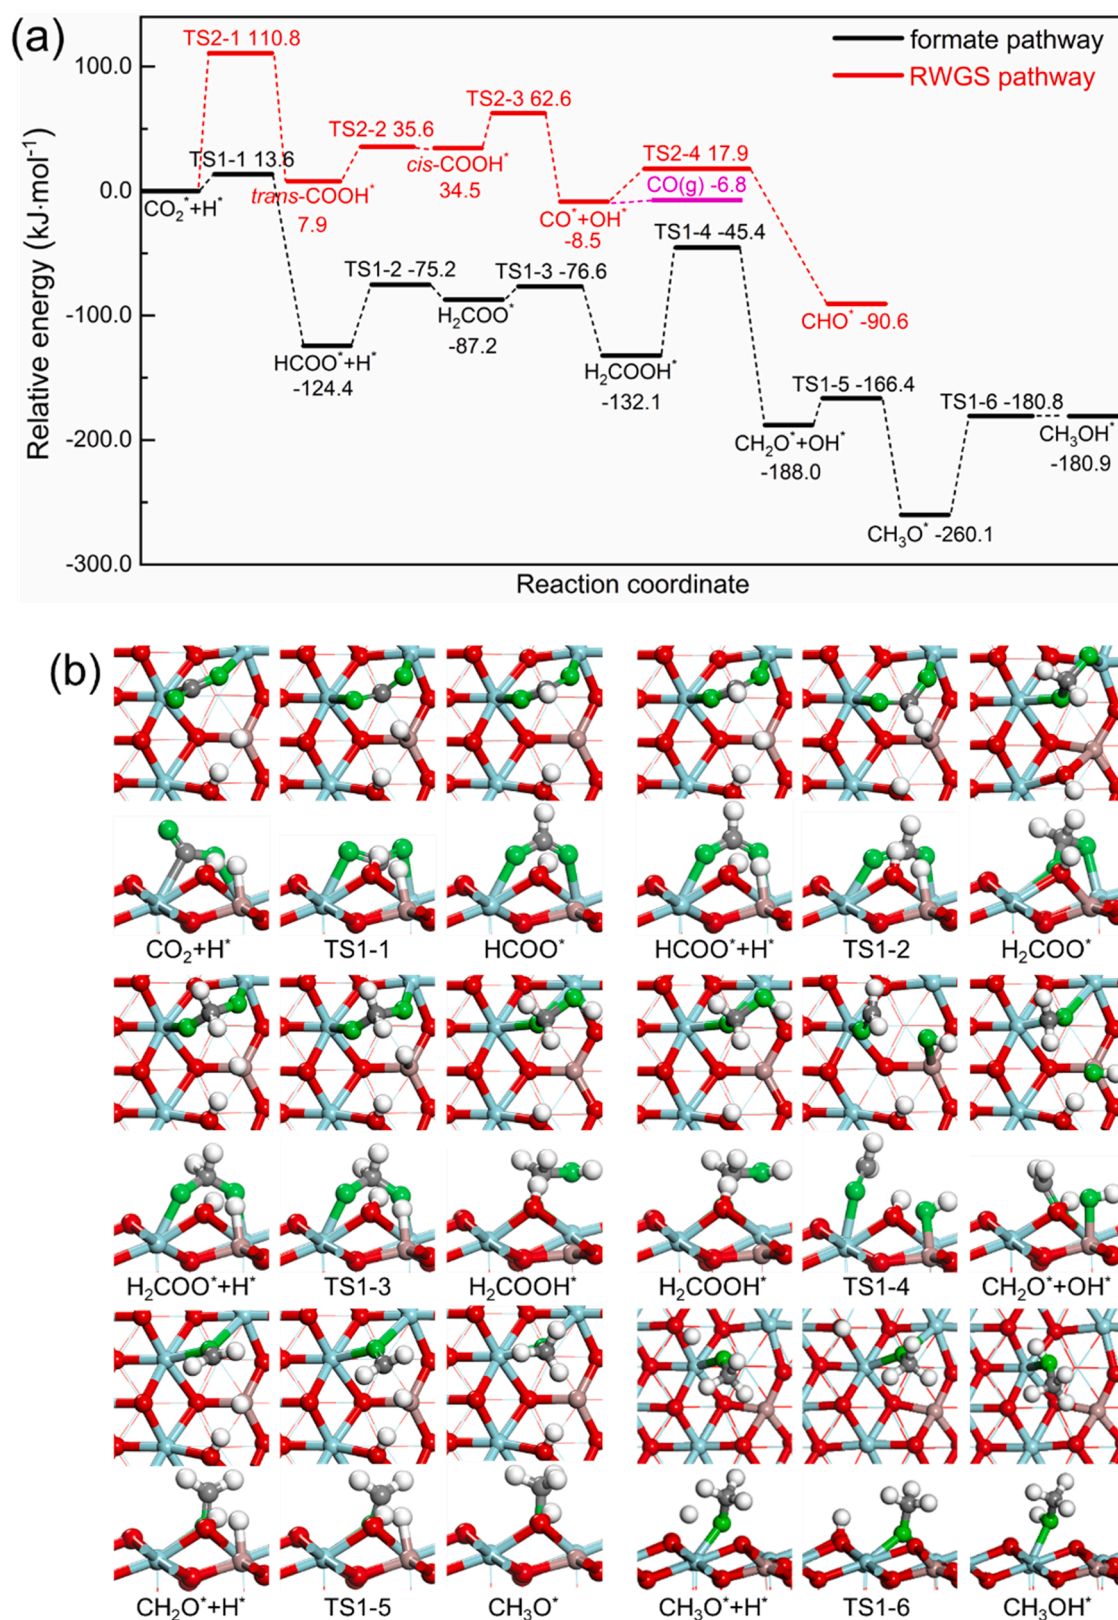

**Fig. 8.** The stable adsorption configurations and differential charge density plots and Bader charge of CO<sub>2</sub> (a) and H<sub>2</sub> species (b) adsorbed on O<sub>V</sub>-GaZrO<sub>x</sub>(101) surface. Blue, brown and white balls represent Zr, Ga and H atoms, respectively. Red and green balls correspond to O atom of catalyst surface and CO<sub>2</sub> species, respectively; Cyan and yellow contours represent electron depression and accumulation, respectively. (For interpretation of the references to colour in this figure, the reader is referred to the web version of this article.)

concluded that the formate pathway, dominantly contributes to the formation of CH<sub>3</sub>O\* intermediate rather than RWGS pathway.

Based on the above discussion, the catalytic mechanism of CO<sub>2</sub> hydrogenation over GaZrO<sub>x</sub>/SAPO-34 catalyst is shown in Fig. 10. Firstly, the CO<sub>2</sub> adsorbs on the surface O<sub>V</sub> near Zr-Zr sites to be activated, and simultaneously, the H<sub>2</sub> adsorbs on adjacent Ga sites to be dissociated, forming Ga-H<sup>δ-</sup> and O-H<sup>δ+</sup>. Activated CO<sub>2</sub> \* could either react with Ga-H<sup>δ-</sup> to form HCOO\* and CH<sub>3</sub>O\* via successive hydrogenation, or combine with O-H<sup>δ+</sup> to form COOH\*, followed by dissociation to form CO (RWGS reaction). The formate pathway for CH<sub>3</sub>O\* formation is competed with RWGS reaction, which is mainly determined by the H<sub>2</sub> dissociation ability of GaZrO<sub>x</sub> oxide. The weak H<sub>2</sub> dissociation ability over GaZrO<sub>x</sub> impedes the hydrogenation of HCOO\*, while the strong H<sub>2</sub> dissociation ability suppresses HCOO\* formation at high temperature. Only the moderate H<sub>2</sub> dissociation ability produced by introduction of optimized Ga to ZrO<sub>2</sub> benefits CO<sub>2</sub> hydrogenation to form and stabilize HCOO\*, and further hydrogenation to CH<sub>3</sub>O\* intermediate at high temperature, the generated CH<sub>3</sub>O\* at high temperature would supply a well temperature compatibility for its further conversion over SAPO-34, which favors the C<sub>2</sub>=C<sub>4</sub> yield.

#### 4. Conclusions

A highly active and selective GaZrO<sub>x</sub>/SAPO-34 bifunctional catalyst for CO<sub>2</sub> hydrogenation into C<sub>2</sub>=C<sub>4</sub> was successfully prepared. Under a condition of 390 °C, 3.0 MPa and 3000 mL·h<sup>-1</sup>·g<sup>-1</sup>, the selectivity for C<sub>2</sub>=C<sub>4</sub> reached 88.8% in hydrocarbons at a high CO<sub>2</sub> conversion of 26.7%, and the light olefin yield is as high as 11.3%. As the Ga:Zr atomic ratio increases, the surface oxygen vacancy content firstly increases from 22.5% to 32.6% and then decreases to 15.4%, while the H<sub>2</sub> dissociation ability gradually increases. CO<sub>2</sub> adsorption ability has a linear relationship with the oxygen vacancy content of the GaZrO<sub>x</sub>, indicating that the oxygen vacancy is the catalytic site of adsorption and activation of CO<sub>2</sub>. The H<sub>2</sub> dissociation ability of GaZrO<sub>x</sub> plays the crucial role for CH<sub>3</sub>O\* intermediate formation and olefin/paraffin ratio, it is found that the weak H<sub>2</sub> dissociation ability over GaZrO<sub>x</sub> impedes the hydrogenation of HCOO\*, while the strong H<sub>2</sub> dissociation ability suppresses HCOO\* formation at high temperature. The moderate H<sub>2</sub> dissociation ability produced by incorporation optimal Ga benefits CO<sub>2</sub> hydrogenation to HCOO\*, and further to CH<sub>3</sub>O\* intermediate via successive hydrogenation at high temperature, while obviously inhibits RWGS

reaction and excessive hydrogenation of C<sub>2</sub>=C<sub>4</sub>, in turn boosting yield of C<sub>2</sub>=C<sub>4</sub>. Mechanistic study shows that formate pathway, dominantly contributes to the formation of CH<sub>3</sub>O\* intermediate rather than RWGS pathway. This work provides a possibility to develop highly active and selective GaZrO<sub>x</sub> combined with other zeolites such as SSZ-39, H-ZSM-5 for synthesis high value-added chemicals (e.g., LPG, liquid fuels, aromatics) from CO<sub>2</sub> conversion.
